THE MASS OF THE *W* BOSON

Revised March 2000 by C. Caso (Univ. of Genova) and A. Gurtu (Tata Inst.)

Till 1995 the production and study of the *W* boson was the exclusive domain of the $\overline{p}p$ colliders at CERN and FNAL. *W* production in these hadron colliders is tagged by a high p_T lepton from *W* decay. Owing to unknown parton–parton effective energy and missing energy in the longitudinal direction, the experiments reconstruct only the transverse mass of the *W* and derive the *W* mass from comparing the transverse mass distribution with Monte Carlo predictions as a function of M_W.

Beginning 1996 the energy of LEP increased to above 161 GeV, the threshold for *W*–pair production. A precise knowledge of the e^+e^- centre of mass energy enables one to reconstruct the *W* mass even if one of them decays leptonically. At LEP two methods have been used to obtain the *W* mass. In the first method the measured *W*–pair production cross sections, $\sigma(e^+e^- \to W^+W^-)$, have been used to determine the *W* mass using the predicted dependence of this cross section on M_W (see Fig. 1). At 161 GeV, which is just above the *W*–pair production threshold, this dependence is a much more sensitive function of the *W* mass than at the higher energies (172 to 202 GeV) at which LEP has run during 1996–99. In the second method, which is used at the higher energies, the *W* mass has been determined by directly reconstructing the *W* from its decay products.
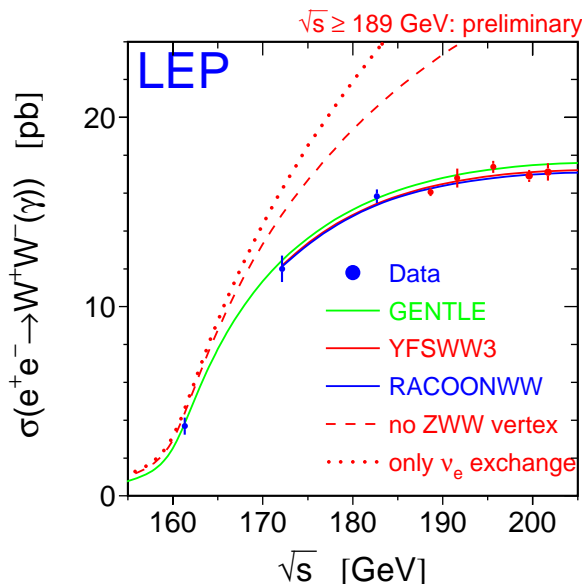

Each LEP experiment has combined their own mass values properly taking into account the common systematic errors. In order to compute the LEP average *W* mass each experiment has provided its measured *W* mass for the *qqqq* and *qqℓν* channels at each center-of-mass energy along with a detailed break-up of errors (statistical and uncorrelated, partially correlated and fully correlated systematics [1]). These have been properly combined to obtain a *preliminary* [2] LEP *W* mass = 80.401±0.048 GeV. Errors due uncertainties in LEP energy (17 MeV) and possible effect of color reconnection (CR) and Bose–Einstein (BE) correlations between quarks from different *W*'s (18 MeV) are included. The mass difference between *qqqq* and *qqℓν* final states (due to possible CR and BE effects) is 35±55 MeV.

The two Tevatron experiments have also carried out the exercise of identifying common systematic errors and averaging with CERN UA2 data obtain an average *W* mass = 80.448±0.062 GeV.

Combining all the published and unpublished p–$\overline{p}$ Collider and LEP results (as of mid-March 2000) yields an average *W*–boson mass of 80.419±0.038 GeV assuming no common systematics between LEP and hadron collider measurements.

The Standard Model prediction from the electroweak fit, excluding the direct *W* mass measurements from LEP and Tevatron, gives a *W*–boson mass of 80.382 ± 0.026 GeV.

OUR EVALUATION in the listing below is obtained by combining only published LEP and p–$\overline{p}$ Collider results using the same procedure as above.
